20 clinical notes

21 Abstract

22 **Background:** Social and behavioral determinants of health (SBDH) are associated with a variety of health and utilization
23 outcomes, yet these factors are not routinely documented in the structured fields of electronic health records (EHR). The
24 objective of this study was to evaluate different machine learning approaches for detection of SBDH from the unstructured
25 clinical notes in the EHR.

26 **Methods:** Latent Semantic Indexing (LSI) was applied to 2,083,180 clinical notes corresponding to 46,146 patients in the
27 MIMIC-III dataset. Using LSI, patients were ranked based on conceptual relevance to a set of keywords (lexicons) pertaining to
28 15 different SBDH categories. For Generative Pretrained Transformer (GPT) models, API requests were made with a Python
29 script to connect to the OpenAI services in Azure, using gpt-3.5-turbo-1106 and gpt-4-1106-preview models. Prediction of
30 SBDH categories were performed using logistic regression model that included age, gender race and SBDH ICD-9 codes with a
31 natural cubic spline of 2 degrees of freedom for age.

32 **Results:** LSI retrieved patients according to 15 SBDH domains, with an overall average PPV \geq 83%. Using manually curated
33 gold standard (GS) sets for nine SBDH categories, the macro-F1 score of LSI (0.74) was better than ICD-9 (0.71) and GPT-3.5
34 (0.54), but lower than GPT-4 (0.80). Due to document size limitations, only a subset of the GS cases could be processed by
35 GPT-3.5 (55.8%) and GPT-4 (94.2%), compared to LSI (100%). Using common GS subsets for nine different SBDH categories,
36 the macro-F1 of ICD-9 combined with either LSI (mean 0.88, 95% CI 0.82-0.93), GPT-3.5 (0.86, 0.82-0.91) or GPT-4 (0.88,
37 0.83-0.94) was not significantly different. After including age, gender, race and ICD-9 in a logistic regression model, the AUC
38 for prediction of six out of the nine SBDH categories was higher for LSI compared to GPT-4.0.

39 **Conclusions:** These results demonstrate that the LSI approach performs comparable to more recent large language models,
40 such as GPT-3.5 and GPT-4.0, when using the same set of documents. Importantly, LSI is robust, deterministic, and does not
41 have document-size limitations or cost implications, which make it more amenable to real-world applications in health systems.

42

43 Background

44 There is growing evidence that Social and Behavioral Determinants of Health (SBDH) are associated with
45 a wide variety of health outcomes and that including SBDH data can improve prediction of health risks.^{1,2}

46 While many studies focus on using neighborhood level SBDH indicators, evidence suggests that using
47 individual-level SBDH significantly improves prediction of outcomes such as medication adherence, risk
48 of hospitalization, HIV risk, suicide attempts, or the need for social work.¹ In contrast, most studies that
49 used external neighborhood-level data showed minimal contribution to individual risk prediction.¹ Currently,

50 documentation of individual-level SBDH is sparse and incomplete in the structured fields within the EHR,³
51 but there are increasing efforts to implement screening tools in clinical workflow to document patient-level
52 SBDH factors.⁴ However, screening tools add a significant burden on the healthcare staff at a time when
53 provider burnout is a major concern.⁵

54 SBDH topics may arise during informal communications between the patient and healthcare provider, which
55 are often documented in the clinical notes rather than the structured fields in the EHR.⁵ As an alternative
56 strategy to screening questionnaires and diagnosis codes, several groups have evaluated SBDH documented
57 in the clinical notes in the EHR. Navathe et al. reported that the highest rates of social characteristics were
58 found in physician notes and that the frequency of six out of the seven social characteristics increased when
59 comparing data from physician notes with billing codes.⁶ Similarly, in a larger study, Hatem et al. reported
60 that the prevalence of SBDH in notes was vastly higher compared to billing codes for social isolation (2.59%
61 vs 0.58%), housing issues (2.99% vs 0.19%), and financial strain (0.99% vs 0.06%).⁷

62 Recent work has focused on developing natural language processing (NLP) and machine learning approaches
63 to extract or infer SBDH from clinical narratives.^{8,9} NLP approaches are rule-based and identify SBDH
64 lexicons (keywords and/or phrases) using keyword matching or regular expressions. Identification of SBDH
65 lexicons and NLP rules require considerable manual refinement.^{10,11} More recently, supervised machine
66 learning approaches have been explored for identification of SBDH from notes, by combining a variety of
67 embedding methods, such as bag-of-words, n-grams, word2vec or Bi-directional Encoder Representation from
68 Transformers (BERT), with supervised classification methods such as support vector machines, random
69 forests, logistic regression, convolutional neural network and feed-forward neural network methods.⁸ More
70 recent methods that combine transformer-based embeddings learned from large volumes of documents (Large
71 Language Models, LLM) and deep learning classifiers have demonstrated superior performance in extracting
72 SBDH from clinical notes.^{12–15} However, these models require training large amount of external data sources
73 and fine-tuning using positive and negative gold standard cases. Thus, these approaches still require a
74 considerable amount of manual effort for fine-tuning and may not be applicable to SBDH factors with
75 low prevalence.⁹ Recent studies explored augmentation of low prevalence SBDH using simulated synthetic
76 data and showed that fine-tuned Flan-T5 models outperformed zero-shot Generative Pretrained Transformer
77 (GPT) models.¹⁶

78 In this study, using the publicly available MIMIC-III dataset,¹⁷ we analyzed all clinical notes for over 46,000
79 patients to identify 15 different SBDH categories using a well-known mathematical approach, called Latent

80 Semantic Indexing (LSI). Using a subset of gold standard patient documents, we compared the performance
81 of LSI with more recent GPT models.

82 **Methods**

83 **Latent Semantic Indexing**

84 The overview of our approach is shown in Figure 1.

85 For each patient, a patient-document was created by concatenating the individual notes sequentially in
86 the same order as present in the database. Terms (keywords) were extracted from patient documents
87 using Text-to-Matrix Generator (TMG) package.¹⁸ Punctuation (excluding hyphens and underscores) and
88 capitalization were ignored. Additionally, articles and other common, non-distinguishing words were filtered
89 out using the SMART stop list.¹⁹ A term-by-patient matrix was created where the entries of the matrix
90 were *tf-idf* weighted frequencies of terms across the patient document collection. Latent semantic indexing, a
91 well-known factorization (Singular value decomposition) was performed on this matrix, subsequent to which
92 each term and patient were represented as numeric vectors in reduced dimensions. The similarity between
93 any two entities was calculated as the cosine between their respective vectors. The details of this process and
94 various applications have been previously described by our group^{20–28} and are documented in Additional file
95 1.

96 A total of 15 SBDH categories were considered, inspired from Social Determinants of Health (SDoH) cat-
97 egories defined by Torres et al.,²⁹ and chronic behavior categories defined by the Center for Medicaid and
98 Medicare Services (CMS).³⁰ The representative keyword for each category was finalized after consultation
99 with a group of care managers. Table 1 lists the categories and their representative keywords while Supple-
100 mentary Table S1 in Additional file 1 also lists the available ICD-9 codes for 9 of the 15 categories. For each
101 keyword, patients were ranked in descending order of the cosine similarity between their truncated vectors.
102 Patients with cosine scores $> Q3 + (3.0 * IQR)$ were assigned to the respective SBDH category. The IQR
103 (interquartile range) was calculated as $Q3$ (75th percentile) – $Q1$ (25th percentile).

104 **Generative Pretrained Transformers (GPT)**

105 All GPT API requests were made using a Python script which uses the "openai" library to connect to the
106 OpenAI services in Azure, using gpt-3.5-turbo-1106 and gpt-4-1106-preview models. The Azure OpenAI

107 Service is a secure enterprise utility that is fully controlled by Microsoft and does not interact with any
108 services operated by OpenAI (e.g. ChatGPT, or the OpenAI API).³¹ Using this platform mitigated any
109 potential risks to data sharing agreements or to patient privacy. Each API call included two components:
110 1) A function definition for the SBDH category, and 2) The contents of a patient document. GPT identifies
111 the presence of the SBDH category in a document based on the name of the function and parameter names,
112 with no other domain-specific information provided to the API. Each SBDH domain had its own function
113 definition in the format of a JSON object (Additional file 1). Below is an example function definition for
114 "Housing Insecurity":

```
115  
116     sbdh_function = {  
117  
118         "name": "identify_housing_insecurity",  
119  
120         "parameters": {  
121  
122             "type": "object",  
123  
124             "properties": {  
125  
126                 "housing_insecurity": {  
127  
128                     "type": "string",  
129  
130                     "enum": ["Yes", "No"]  
131  
132                 }  
133  
134             }  
135  
136         },  
137  
138         "required": ["housing_insecurity"]  
139  
140     }
```

130 Sending a function ensures that the response from the API will be a predictable, well-formed JSON object
131 with a binary answer of "Yes" or "No" to indicate the presence of the SBDH category in the patient document.
132 The GPT engine does not actually call the function but instead treats the function like a callback, where
133 the response from GPT includes the "Yes" or "No" value of the function parameter. The Python script calls
134 the API as follows, including the patient document and the domain function as arguments:

```
135  
136     response = openai.ChatCompletion.create(  
137  
138     engine = "gpt model name",  
139  
140     messages = [{"role": "user", "content": "Contents of patient  
141  
142     document here..."}],
```

```
1444     functions = [sbdh_function],
1445     function_call = {"name": "identify_housing_insecurity"},
1446     temperature = .01
1447 )
1448
```

1449 The "temperature" argument controls the determinism of the GPT model, accepting a value between 0
1450 (more deterministic) and 2 (less deterministic). The API call and SBDH function definitions are identical
1451 for GPT-3.5 and GPT-4. All prompts were zero-shot, with no fine-tuning examples provided in the prompt.

1452 **Analysis and Evaluation**

1453 The patient rankings pertaining to each SBDH keyword query was evaluated manually by chart review
1454 to determine the positive predictive value (PPV) of the top 10, median 10 and last 10 ranked. SBDH
1455 classification performance was evaluated using precision, recall and F1 score on manually curated gold
1456 standard (GS) samples. A random sample of up to 20 ICD-9 coded (when applicable) and up to 20 LSI-
1457 predicted cases were balanced with an equal number of non-coded and non LSI-predicted cases for each of
1458 the nine SBDH categories (that had at least six ICD-9 coded patients). This resulted in random samples
1459 ranging from 46 (financial circumstances) to a maximum of 80 (Tobacco use, Alcohol abuse and Opiate
1460 abuse). All cases were manually evaluated by chart review to determine actual positive (P) and negative (N)
1461 cases. Supplementary Table S3 in Additional file 1 includes the summary characteristics of the GS samples
1462 for each SBDH category. The performance of the text-based approaches was evaluated by Precision, Recall
1463 and F1 score.

1464 To determine the overall performance of the text-based predictions using either LSI or GPT-4 in addition
1465 to ICD-9 coding, we used a logistic regression model including age, gender, race and ICD-9 for binary
1466 classification of GS patients corresponding to each SBDH category. In all three models, age was fit using
1467 a cubic spline with 2 degrees of freedom. The performance of each model was evaluated by 10-fold cross-
1468 validation and the Area Under the Receiver Operating Curve (AUROC).

1469 **Results**

1470 A number of previous studies have demonstrated that International Disease Classification (ICD) codes cor-
1471 responding to social and behavioral determinants of health are not commonly used in the EHR.⁷ Similarly,

168 analysis of the MIMIC-III dataset showed that out of 44 potential Social Determinants of Health (SDoH)
 169 ICD-9 codes,²⁹ only 17 were used in MIMIC-III and only nine SDoH categories were assigned to three or
 170 more patients (Supplementary Figure S1 in Additional file 1). To develop a comprehensive set of SBDH for
 171 benchmarking the text-based approaches, we included the following SDoH categories in order of frequency:
 172 *Lack of housing* (202), *history of physical abuse* (37), *unemployment* (15), *legal circumstances* (13), *inade-*
 173 *quate material resources* (6). In addition, we included four behavioral chronic conditions defined by CMS³⁰
 174 and several other SBDH categories such as suicide ideation and compliance, which are represented in ICD-10
 175 but not in ICD-9. Altogether, this study focused on 15 SBDH categories (Table 1), although only nine
 176 categories were documented by ICD-9 billing codes in this data set (Supplementary Table S1 in Additional
 177 file 1).

Table 1: Performance of LSI predictions of SDBH categories. The terms in parentheses indicate the query word used to rank all patients in the dataset.

| SBDH Category (Keyword Query) | ICD Coded N | Predicted N | PPV of LSI Predictions | | | |
|-------------------------------------------|-------------|-------------|------------------------|-----------|-----------|---------|
| | | | Top 10 | Median 10 | Bottom 10 | Average |
| Tobacco use disorder (Smokes) | 3005 | 2195 | 100% | 90% | 80% | 90% |
| Alcohol abuse (EtOH) | 2988 | 1080 | 100% | 100% | 100% | 100% |
| Drug abuse (Opiate) | 672 | 444 | 100% | 60% | 50% | 70% |
| Drug abuse (Cocaine) | 545 | 1852 | 100% | 70% | 40% | 70% |
| Housing insecurity (Homeless) | 202 | 470 | 100% | 80% | 70% | 83% |
| Physical/Sexual abuse (Abused) | 37 | 121 | 80% | 50% | 30% | 53% |
| Financial insecurity (Unemployed) | 15 | 809 | 100% | 90% | 100% | 97% |
| Legal Circumstances (Legal) | 13 | 1052 | 80% | 50% | 20% | 50% |
| Financial circumstances (Financial) | 6 | 402 | 100% | 60% | 90% | 83% |
| Compliance (Noncompliant) | 0 | 402 | 100% | 100% | 90% | 97% |
| Mobility issues (Walker) | 0 | 3235 | 90% | 100% | 90% | 93% |
| Lack of English proficiency (Interpreter) | 0 | 1621 | 100% | 90% | 80% | 90% |
| Caregiver dependency (Caretaker) | 0 | 443 | 100% | 90% | 60% | 83% |
| Suicidal ideation (Suicide) | 0 | 1090 | 100% | 60% | 40% | 67% |
| Lack of transportation (Transportation) | 0 | 452 | 60% | 70% | 70% | 67% |

178 Latent Semantic Indexing and Lexicon Development

179 Latent Semantic Indexing (LSI) is a well-known matrix factorization method, which reduces the dimension-
 180 ality of terms and documents in to lower rank matrices.²⁰⁻²⁸ By using a lower rank matrix, the terms can
 181 be grouped together more conceptually, whereas by using higher ranks, terms can be grouped more literally.
 182 In addition, patients can be grouped together in more conceptual or literal fashion based on the content in
 183 their clinical notes.

184 Out of a total of 46,520 patients in the MIMIC-III dataset, 46,146 patients had clinical notes. The number

185 of notes associated with these patients ranged from 1 to 1420, with the median being 21 notes. A patient
186 document was constructed by concatenating all clinical notes together for each patient, which resulted in a
187 term dictionary of >300,000 terms. To reduce the dictionary size to terms that are relevant to SBDH, we
188 filtered the dictionary to include only terms that were extracted from social history sections, resulting in a
189 final dictionary size of 26,237 terms. Each term in the 26,237 terms-by- 46,146 patients matrix was weighted
190 using *tf-idf* and then factorized to 12,723 dimensions (see Additional file 1 for details).

191 To determine the best lexicons (terms) to represent various SBDH categories, we manually constructed a set
192 of 134 keywords (including variants, plurals and common misspellings) corresponding to the SBDH categories
193 described above (Supplementary Table S2 in Additional file 1). Both the SBDH categories and the lexicons
194 were iteratively refined as described below based on: 1) The correlations between terms with respect to the
195 vector of all ranked patients in the MIMIC-III dataset (Figure 2a), 2) the precision of the top ranked patients
196 for the keyword query, 3) the recall of ICD-9 coded patients.

197 Clustering of the term correlations revealed groups of highly synonymous terms deduced from the word usage
198 patterns in the patient documents. This demonstrates the utility of matrix factorization as an unsupervised
199 machine learning approach which learns conceptually related terms based on the word usage patterns in the
200 clinical notes. For example, factorization revealed that words such as intoxicated/intoxication, crack/cocaine,
201 or manic/mania are synonymously used in the clinical notes (Figure 2b). In addition, this approach identified
202 short phrases in a rudimentary way, such as legal/guardian (Figure 2b). Lastly, some of the larger clusters
203 included broader contextual information, such as suicide/overdose/psych/suicidal/psychiatrist (Figure 2c).

204 **Evaluation of LSI-derived SBDH Predictions**

205 All patients in the collection were ranked based on a representative keyword query for each of the 15 SBDH
206 categories. Application of interquartile outlier detection method determined the cosine threshold for each
207 query where the patients ranked above the threshold ($> Q3 + (3.0 * IQR)$) are highly associated with the
208 query and thus predicted to have the specific SBDH. In all but three SBDH categories (Tobacco use, Alcohol
209 abuse, and Drug abuse - Opiate), the number of patients in the collection with an LSI-predicted SBDH were
210 substantially higher than the ICD-9 coded patients (Table 1).

211 To evaluate the classification performance of the SBDH predictions, we determined the PPV by manual
212 evaluation of the top 10, median 10, and bottom 10 patients within the cut-off threshold (Table 1). In all
213 but four SBDH categories, the PPV of the top 10 ranked patients was 100%. As expected, the PPV decreased

214 with lower rankings. The average PPV for all 15 SBDH categories ranged from 50% (legal circumstances)
 215 to 100% (alcohol abuse), with nine of the SBDH categories having a PPV \geq 83%.

216 Next, we compared the performance of ICD-9 coding with either LSI, GPT-3.5 or GPT-4 large language
 217 models using different sets of gold standard (GS) patients that were randomly selected for each SBDH
 218 category and manually labeled by chart review. The characteristics of the GS sets of patients for each SBDH
 219 category are provided in Supplementary Table S3 in Additional file 1. Only nine SBDH categories that had
 220 at least six ICD-9 coded patients were included in this analysis. Importantly, only LSI was able to process
 221 all of the patient documents. In contrast, due to context window size restrictions, GPT-3.5 processed 55.6%
 222 of the gold standard documents and GPT-4 processed 94.2% (Figure 3).

223 Earlier versions of GPT were highly irreproducible such that the same prompt could produce different
 224 responses or no response at all. To evaluate this phenomenon, we compared the responsiveness of GPT-
 225 3.5 and GPT-4 to the same set of shared documents within the 16K context window limit of GPT-3.5 for
 226 each of the nine SBDH categories (Table 2). For GPT-3.5, the same set of documents were submitted
 227 using the same prompt five independent times. GPT-3.5 was unresponsive for 2% (Cocaine use) to 30%
 228 (unemployed) of the patient documents across the SBDH categories. In addition, in all but one SBDH
 229 category, GPT-3.5 provided conflicting responses between the five independent prompts. For example,
 230 although GPT3.5 provided responses for all 27 patient documents related to legal circumstances, it provided
 231 conflicting responses for six (22%) of the patient documents (Table 2). In contrast, GPT-4 was unresponsive
 232 for only two documents (3.8%) in only one SBDH category (tobacco use).

Table 2: Unresponsiveness of GPT-3.5 and GPT-4. On a set of shared patient documents (N), GPT-3.5 was prompted five independent times, whereas GPT-4 was prompted only once. The % of documents where GPT-3.5 or GPT-4 did not provide a response is indicated for each SBDH category. The % disagreement corresponds to the number of documents where GPT-3.5 provided conflicting binary responses.

| SBDH Category | N | GPT-3.5 | | GPT-4 |
|-------------------------|----|----------------|---------------|---------------|
| | | % Disagreement | % No Response | % No Response |
| Housing insecurity | 48 | 6.3% | 0.0% | 0.0% |
| Tobacco use | 52 | 3.8% | 15.4% | 3.8% |
| Opiate abuse | 42 | 7.1% | 0.0% | 0.0% |
| Alcohol abuse | 41 | 2.4% | 0.0% | 0.0% |
| Cocaine use | 51 | 0.0% | 2.0% | 0.0% |
| Physical & sexual abuse | 39 | 2.6% | 5.1% | 0.0% |
| Unemployed | 30 | 6.7% | 30.0% | 0.0% |
| Legal circumstances | 27 | 22.2% | 0.0% | 0.0% |
| Financial circumstances | 22 | 13.6% | 4.5% | 0.0% |

233 As expected, due to the limitations described above, the average recall of GPT-3.5 across all of the documents

234 in all nine SBDH categories was low (0.41), compared to LSI (0.70) and GPT-4 (0.77) (Table 3). Overall,
235 the average macro-F1 was highest for GPT-4 (0.8), followed by LSI (0.74), ICD-9 (0.71) and GPT-3.5 (0.54)
236 despite the fact that GPT-4 was unable to process 5.8% of the documents due to context window size
237 limitations (Figure 3 & Table 3).

238 It is important to note that in some cases, although a patient was assigned an ICD-9 code for a particular
239 SBDH, supporting documentation in the clinical notes could not be found. In such cases, the ICD-9 coded
240 individuals were assumed to be actual positives. Therefore, to retrieve all possible SBDH in a given GS
241 set, the text-based prediction of SBDH was combined with ICD coded individuals across the nine SBDH
242 categories. On average, all three methods performed similarly with respect to precision, recall and F1 when
243 combined with ICD-9 (Figure 4).

244 Lastly, to evaluate the overall predictive performance of LSI with GPT-4 when combined with ICD-9 coding,
245 we compared the prediction AUC of three different logistic regression models: 1) base model including
246 gender, age, race and SBDH ICD-9 codes, 2) base model plus LSI identified SBDH, 3) base model plus
247 GPT-4 identified SBDH (Figure 5). Using only ICD-9 coding (base model), the AUCs for the nine SBDH
248 categories ranged between 0.69 (*housing insecurity* and *financial circumstances*) to 0.85 (*history of physical*
249 *and sexual abuse*). In all nine categories, inclusion of LSI or GPT-4 improved the AUCs compared to
250 ICD-9. Interestingly, LSI outperformed GPT-4 in six of the nine SBDH categories (*housing insecurity*,
251 *unemployment*, *opiate abuse*, *alcohol abuse*, *legal circumstances*, and *financial circumstances*).

Table 3: Retrieval performance of each method alone using a set of sampled Gold Standard cases. The bold text indicate the highest precision, recall, or F1 for each SBDH category (row).

| SBDH Category | Sampled N (P) | Precision | | | | Recall | | | | F1 | | | |
|-------------------------|------------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|-------------|
| | | ICD- 9 | LSI | GPT- 3.5 | GPT- 4 | ICD- 9 | LSI | GPT- 3.5 | GPT- 4 | ICD- 9 | LSI | GPT- 3.5 | GPT- 4 |
| Housing insecurity | 80 (53) | 0.85 | 0.95 | 0.78 | 0.92 | 0.64 | 0.72 | 0.47 | 0.62 | 0.73 | 0.82 | 0.59 | 0.74 |
| Tobacco use | 80 (56) | 0.95 | 0.93 | 0.89 | 0.88 | 0.68 | 0.66 | 0.43 | 0.93 | 0.79 | 0.77 | 0.58 | 0.90 |

252 Discussion

253 In this study, we demonstrated the utility of LSI as a robust unsupervised approach for comprehensively
254 processing all clinical notes in the EHR to identify SBDH and to supplement the SBDH documented by
255 ICD-9 diagnosis codes. Importantly, we show that although LSI is a bag-of-words approach, it performed
256 similarly and sometimes better than GPT models. This work highlights several advantages for using LSI in
257 real-world healthcare applications.

258 One major advantage of LSI is its ability to process all of the notes for a given patient without the imposed
259 context window token size limitations of GPT. As pointed out in Figure 3, only 55.6% and 94.2% of the
260 GS cases could be processed by GPT-3.5 and GPT-4, respectively. At the time of our analysis, the input
261 context window size limits for GPT-3.5 and GPT-4 were 16K and 128K tokens, respectively. However,
262 other LLMs may have larger context windows. Even with the context window limits, it is possible to
263 process larger documents by ‘chunking’, a method where a large document is split into smaller overlapping
264 documents that are smaller than the token limits. In our analysis, we did not attempt to process all of the
265 GS documents, instead we directly compared the performance of LSI with GPT-3.5 and GPT-4 using the
266 same set of documents (Table 3 and Figures 4 & 5). Another reason for limiting the analysis to a subset of
267 GS documents was cost. At the time of the analysis, the cost for GPT-3.5 and GPT-4 using the Microsoft
268 Azure OpenAI³¹ services per query was USD \$0.001 and \$0.01 per 1K input tokens, respectively. Thus,
269 it would have been more costly to chunk the larger GS documents. Another way to reduce the number of
270 GPT queries would have been to perform multi-class labeling. In our analysis, we performed single class
271 labeling, where each document was processed individually to identify a single SBDH category. Although this
272 approach would be useful, it may require considerable fine-tuning and may not be feasible for identifying all
273 15 SBDH categories at once.

274 Another major advantage of LSI is that it does not require external training on a large dataset and fine-
275 tuning for domain specific applications. For this study, the LSI model was built using all of the clinical
276 notes for all of the > 46,000 patients at once. In contrast, GPT and other LLM require extensive training
277 using large amounts of external data sources. For example, GPT 3.5 was trained on 175 billion parameters
278 using training data up to September 2021. Although the models perform well for general text analysis,
279 they may not perform well on specialized clinical tasks. For example, Lybarger et al. developed an event
280 based deep-learning extractor for SBDH that determines chronicity, duration, frequency and type of event.¹²
281 However, their models apply only to a subset of SBDH categories, including employment, living status, as

282 well as alcohol, tobacco and drug use. They point out that training these models required significant manual
283 effort by human experts to develop both positive and negative gold standard datasets for fine-tuning.¹² In
284 addition, since these methods require large amounts of training data for fine-tuning, they can have limited
285 usefulness for SBDH categories that are rare (low prevalence).

286 Another major advantage of LSI is that, unlike GPT, it is deterministic (reproducible) and 100% responsive
287 to all queries. For a given factorization rank, LSI produces the same exact ranking of the documents based
288 on the same query. On the other hand, we showed (Table 2) that GPT-3.5 produces conflicting responses to
289 the same prompt on the same set of documents. Moreover, we demonstrated that both GPT-3.5 and GPT-4
290 may not respond, a phenomenon commonly referred to as ‘laziness’. Although the GPT-4 model has been
291 improved to reduce laziness, we found that it can be unresponsive as the document size reaches its maximum
292 context window size limits.

293 Our findings indicate that using clinical notes to identify SBDH should not replace efforts in health systems
294 to screen for SBDH, rather provide a complementary approach to enhance estimates of the SBDH burden
295 (prevalence) in large populations. During chart review for developing the GS sets, we found a few ICD-9
296 coded individuals who had no supporting documentation for the codes. For example, some patients had
297 few encounters with the health system and had no social history notes, yet were coded for homelessness or
298 alcohol abuse. As reported by others, this observation illustrates the importance of combining the information
299 provided by ICD-9 codes and other structured data (e.g., questionnaires) with unstructured data in the EHR
300 to obtain a more representative assessment of the SBDH prevalence in a population.^{7,10–12,32} On the other
301 hand, implementing SDoH screening tools across a large health system is impractical and potentially biased.
302 Studies have shown that SDoH screening forms are primarily implemented in outpatient and primary care
303 settings. However, it is thought that socioeconomically disadvantaged individuals are less likely to go to
304 primary care, instead use the emergency department (ED) for their healthcare needs.³³ Moreover, a recent
305 study demonstrated that only 3.7% of the patients in a large health care system in South Carolina had
306 answered all 11 questions on the SDoH screening forms.³⁴ Therefore, for better assessment of SBDH burden
307 in a population, information must be aggregated from a variety of sources in the EHR, including the clinical
308 notes.

309 It is worth highlighting that the costs associated with OpenAI services make it currently unrealistic to
310 implement in health systems to assess SBDH burden in large populations of patients. To address this issue,
311 future research will focus on using LSI to narrow large populations of patients into smaller groups that

312 are conceptually predicted to have SBDH and then process those documents using GPT to contextualize
313 and validate the LSI predictions. Factorization provides value beyond keyword searching alone because it
314 contextualizes keywords as vectors in reduced ranked space, thereby grouping words that are frequently used
315 together in the context of SBDH keywords. This approach provides a general advantage by automatically
316 grouping synonyms, misspellings, and conceptually related terms that are often used together in narratives
317 (Figure 2). For example, a homeless individual is often unemployed and has drug/alcohol abuse problems.
318 Also, factorization is able to infer that ‘shelter’ and ‘homelessness’ are synonymously used in the narratives.
319 By lowering the rank of the factorized matrix, one can identify a subset of patients who are conceptually
320 related to the SBDH, achieving higher recall than precision. By subsequently processing these patient
321 documents with GPT-4, the specific evidence in support of the SBDH can be readily deduced while keeping
322 the overall processing cost low.

323 While LSI was highly sensitive (high PPV) for most SBDH categories, its performance was limited for
324 a few SBDH categories such as legal circumstances. We found that legal circumstances covered a broad
325 range of areas ranging from power of attorney, guardianship issues, hospital liability to encounters with
326 law enforcement for illegal activities. More refinement would be necessary to evaluate the performance of
327 our approach on specific areas pertaining to specific legal circumstances. For example, guardianship issues
328 for clinical decision making could be better identified with a ‘guardian’ query rather than a general term
329 such as ‘legal’. In three cases (alcohol abuse, tobacco use, and opiate abuse), our approach identified fewer
330 cases than ICD coded individuals. This may be due to the fact that drug, alcohol and tobacco use are
331 routinely captured within structured fields in current clinical practice. However, other SBDH categories are
332 not routinely captured. One approach to increase the number of cases identified by our approach would be
333 to relax the thresholding parameter or to combine multiple lexicons representing alcohol abuse in an additive
334 way.

335 Feller et al. were among the first groups to apply NLP methods to infer SBDH from clinical notes. After
336 feature selection, they included 2-4,000 individual words as independent variables in various machine learning
337 classifiers to identify sexual history, sexual orientation, alcohol use, substance use and housing status. They
338 found that combining clinical notes and structured data enabled reasonably accurate inference of these SBDH
339 categories.^{35,36} Bejan et al., using a vector embedding approach to expand SDoH lexicons, demonstrated
340 better performance of identification of homelessness and adverse childhood experiences (ACEs) from clinical
341 notes.³⁷ Our process, which combines the bag-of-words approach with factorization for embedding, allows

342 an automated method to identify a broad set of SBDH categories.

343 The LSI approach has several limitations. First, it is a bag-of-words embedding technique, which does not
344 account for word context (phrases) and negated terms. In addition, the performance of our approach was
345 affected by the presence of forms and templated text in the clinical notes, such as “Family Information” or
346 social history forms, where there are many negations and repeated text. The performance of our approach
347 would improve if certain note types, forms and templates were removed during pre-processing. Lastly, our
348 approach does not provide temporal relations and event-types. As stated above, many of these limitations
349 would be addressed by combining the advantages of LSI (e.g., robustness, determinism, and no cost) with
350 the advantages of LLM (i.e., contextualization, removal of negation, and multi-label classification).

351 **Conclusions**

352 In this study, we demonstrated that using an unsupervised machine learning factorization approach on
353 clinical notes is a robust way to enhance SBDH identification from the EHR. This work is significant because
354 it provides an automated way to extract SBDH for patients in a health system without the additional burden
355 of implementing standardized surveys in clinical workflows. By providing better estimates of SBDH burden
356 in populations, this work sets the stage for developing patient level health risk and utilization prediction
357 models that incorporate SBDH factors in addition to standard clinical and structured data from the EHR.
